WHAT'S KNOWN ON THIS SUBJECT: Virtually all persons in industrialized countries are exposed to bisphenol A (BPA), and early-life BPA exposure might be associated with behavior problems. Few human studies have been conducted, and the impact of gestational versus childhood BPA exposures is unclear.

WHAT THIS STUDY ADDS: BPA exposure during pregnancy, but not childhood, was associated with worse behavior at 3 years of age, especially among girls. Domains related to behavioral and emotional regulation were most affected by gestational BPA exposure.

abstract

OBJECTIVES: To estimate the impact of gestational and childhood bisphenol A (BPA) exposures on behavior and executive function at 3 years of age and to determine whether child gender modified those associations.

METHODS: We used a prospective birth cohort of 244 mothers and their 3-year-old children from the greater Cincinnati, Ohio, area. We characterized gestational and childhood BPA exposures by using the mean BPA concentrations in maternal (16 and 26 weeks of gestation and birth) and child (1, 2, and 3 years of age) urine samples, respectively. Behavior and executive function were measured by using the Behavior Assessment System for Children 2 (BASC-2) and the Behavior Rating Inventory of Executive Function-Preschool (BRIEF-P).

RESULTS: BPA was detected in >97% of the gestational (median: 2.0 $\mu\text{g/L}$) and childhood (median: 4.1 $\mu\text{g/L}$) urine samples. With adjustment for confounders, each 10-fold increase in gestational BPA concentrations was associated with more anxious and depressed behavior on the BASC-2 and poorer emotional control and inhibition on the BRIEF-P. The magnitude of the gestational BPA associations differed according to child gender; BASC-2 and BRIEF-P scores increased 9 to 12 points among girls, but changes were null or negative among boys. Associations between childhood BPA exposure and neurobehavior were largely null and not modified by child gender.

CONCLUSIONS: In this study, gestational BPA exposure affected behavioral and emotional regulation domains at 3 years of age, especially among girls. Clinicians may advise concerned patients to reduce their exposure to certain consumer products, but the benefits of such reductions are unclear. *Pediatrics* 2011;128:873–882

Bisphenol A (BPA) is used in a variety of consumer products, including dental sealants, food/beverage containers and linings, medical equipment, and thermal receipts.¹ The use of BPA-containing products in daily life makes exposure ubiquitous in industrialized and industrializing countries.^{2–5} The predominant source of BPA exposure for most people is diet, although exposure also might occur through inhalation or dermal absorption, which results in substantial exposure among persons involved in the manufacture or handling of BPA-containing products.^{6–10}

BPA might disrupt the endocrine system.¹¹ Experimental studies with animals indicated that gestational BPA exposure disrupts normal neurodevelopment, affecting sexually dimorphic behaviors such as aggression, anxiety, exploration, and spatial memory.^{12–14} Sexually dimorphic clinical disorders such as attention-deficit/hyperactivity disorder, autism, and depression might be clinical correlates of these animal behaviors and might be related to early-life disruption of the endocrine system.^{15,16} These observations suggest that sexually dimorphic behavioral traits may serve as sensitive end points in epidemiological studies.

We reported previously that gestational BPA exposure was associated with increased hyperactivity and aggression scores for 2-year-old girls in a prospective birth cohort from Cincinnati, Ohio.² However, important questions remain about these findings. The children were young, and the observed associations might not persist with continued development. Furthermore, our previous study was unable to examine the relationship between BPA exposure and executive function, which is a set of processes involved in inhibiting behavior, modulating emotions, and shifting between activities.

Deficits in executive function are a feature of disorders such as attention-deficit/hyperactivity disorder.¹⁷ Finally, we did not examine the impact of infant/childhood BPA exposures on neurobehavior.

Additional research examining the neurotoxicity of BPA is needed, given the pervasiveness of exposure and the potential for even small effects to have substantial public health consequences.^{1,18} The purpose of this study was to determine whether previously observed associations remained at 3 years of age, whether executive functions were affected by BPA exposure, and whether gestational or childhood BPA exposures had greater effects on neurobehavior.

METHODS

Data Source

Data for this study were collected from mothers and their children who were participating in the Health Outcomes and Measures of the Environment Study, a prospective birth cohort in the Cincinnati, Ohio, metropolitan area designed for the study of low-level environmental toxicant exposures.¹⁹ Eligibility criteria and enrollment of this cohort were described previously.²

Urinary BPA Concentrations

Three maternal spot urine samples were collected between March 2003 and January 2006, twice during pregnancy, at ~16 and ~26 weeks of gestation, and within 24 hours after birth. Children's spot urine samples were collected at 1, 2, and 3 years of age, during clinic or home visits, between 2004 and 2009. Preference was given to samples collected during home visits because collection conditions were more standardized. Urine was collected directly into polypropylene specimen cups or, for non-toilet-trained infants, first into Kendall abdominal pads placed inside the diaper.

Urine was stored at or below -20°C until analysis. Diaper inserts contaminated with stool were not analyzed.

The concentrations of total (free plus conjugated) species of BPA were measured at the Centers for Disease Control and Prevention (CDC), by using modified analytical chemistry methods described previously.²⁰ The limit of detection (LOD) was $0.4\ \mu\text{g/L}$; concentrations below the LOD were given a value of $\text{LOD}/\sqrt{2}$.²¹

We characterized gestational and childhood BPA exposures by using the mean of ≥ 2 urine samples from the respective periods (ie, gestation or childhood), because individual urinary BPA concentrations vary and a single measure may misclassify exposure.²² We corrected for urine dilution by using urinary creatinine concentrations and calculated creatinine-standardized BPA concentrations (versus nonstandardized) by dividing individual urinary BPA concentrations by creatinine concentrations before calculating the mean.

Childhood Behavior and Executive Function

Children's behavior was assessed at 3 years of age by using the Behavior Assessment System for Children 2 (BASC-2) Parent Rating Scale for preschoolers. The BASC-2 is a valid, reliable, 134-item, parent-report assessment of a child's problem behaviors in community and home settings.²³ We focused on clinical subscales because they might be more relevant to human behaviors and more comparable to behavioral end points used in animal studies.²⁴ The analyzed subscales included aggression, attention, hyperactivity, depression, anxiety, and somatization.

Children's executive functions at 3 years of age were assessed by using the Behavior Rating Inventory of Exec-

utive Function-Preschool (BRIEF-P), a reliable, valid, 63-question, parent-report inventory.²⁵ Our analyses focused on 5 clinical scales from the BRIEF-P; emotional control scores assess the ability to modulate emotions, inhibit scores reflect the capacity to control behavioral responses, plan/organize scores assess the ability to anticipate and to plan for future events, to set goals, and to grasp main ideas, shift scores measure the capacity to transition to and from events, and working memory scores measure the ability to hold information in mind for completing a task.

Parents were unaware of their own or their children's urinary BPA concentrations when they completed the 2 behavioral measures. Scores on the BASC-2 and BRIEF-P were normalized to a mean of 50 (SD: 10) by the test publishers. For both instruments, higher scores indicate more impairment. Subscales of the BASC-2 and BRIEF-P share a moderate degree of correlation (Pearson $R = 0.5-0.7$), and each test has been used to validate the other.^{25,26} We also used 2 summary scores from the BASC-2 (Behavioral Symptom Index) and BRIEF-P (Global Executive Composite) to describe the study sample and how behavior varied according to child and family characteristics.

Covariates

We included the following potential confounding variables in our exposure-outcome statistical models.^{22,27} Demographic variables (mother's race, education, marital status, and household income) were measured by trained interviewers during pregnancy. Perinatal variables included maternal depressive symptoms measured at 20 weeks of gestation by using the Beck Depression Inventory II.²⁸ The caregiving environment was measured through administration of the

Home Observation for Measurement of the Environment during the 1-year home visit.²⁹

We controlled for gestational exposure to low molecular weight phthalates (compounds used in personal care products and other consumer products) and tobacco smoke by using metabolite concentrations from maternal urine and serum measurements, respectively. We calculated the mean concentrations of cotinine (a metabolite of nicotine) or low molecular weight phthalates from ≥ 2 samples collected during pregnancy or at birth. We used the summed molar concentrations of 3 low molecular weight phthalate metabolites, on the basis of their previous associations with childhood behavior and executive function.³⁰ Metabolite concentrations were quantified at the CDC by using previously described methods.^{31,32}

Statistical Analyses

We began by describing Global Executive Composite and Behavioral Symptom Index scores according to sociodemographic factors. We also examined univariate characteristics of urinary BPA concentrations. We calculated Pearson correlation coefficients between pairs of \log_{10} -transformed urinary BPA concentrations, to gauge their variability.

We fit 3-knot, restricted, cubic splines to examine the dose-response relationship and to examine model linearity assumptions for urinary BPA concentrations and neurobehavior.³³ Restricted cubic polynomial splines allow the shape of the relationship between the exposure and outcome to be flexible and not inherently linear. We used multivariate linear regression to estimate the unadjusted and adjusted changes in BASC-2 and BRIEF-P scores with each 10-fold increase in urinary BPA concentrations during gestation or childhood. We also included the

child's gender and a product interaction term between BPA variables and child gender because our previous findings suggested that child gender modified the association between gestational BPA concentrations and neurobehavior.² We examined the P values for this interaction term and considered values of $<.10$ to be indicative of modification, because our statistical power was limited by sample size.³⁴

Secondary Analyses

First, we examined whether the mutual adjustment for gestational and childhood urinary BPA concentrations changed the pattern of our results. Second, we examined whether additional adjustment for maternal IQ (Wechsler Abbreviated Scales of Intelligence), parity, or duration of breastfeeding (postnatal models only) changed the pattern of observed results.³⁵ Third, we examined whether missing data biased our results by analyzing data for the subsets of women and children who had all 3 urine samples during gestation and childhood, respectively. Finally, we determined whether the exclusion of dilute or concentrated urine samples changed our results.³ Dilute urine was defined as that with creatinine concentrations of <20 mg/dL for mothers and <2 mg/dL for children. Concentrated urine was defined as that with creatinine concentrations of >200 mg/dL for mothers, >128 mg/dL for 1- and 2-year-old children, and >150 mg/dL for 3-year old children.³⁶

Ethical Considerations

The institutional review boards of Cincinnati Children's Hospital Medical Center, the cooperating delivery hospitals, and the CDC approved this study. All mothers provided written informed consent for themselves and their children before enrollment in the study.

RESULTS

Descriptive Statistics

Of the 468 enrolled women, 67 dropped out before delivery, 9 delivered twins, and 3 experienced stillbirths. We also excluded 1 woman with a urinary BPA concentration of 1250 $\mu\text{g/L}$.³⁷ Among the remaining 388 mother-child pairs, 262 (67%) completed follow-up assessments at 3 years of age, and 245 of those mother-child pairs had gestational or childhood BPA exposure measurements and complete covariate data. Among those women, 239 completed the BASC-2 and 237 completed the BRIEF-P.

Dyads with complete follow-up data were more likely to be white, married, 25 to 34 years of age, more educated, and wealthier, compared with dyads with incomplete data (results not shown). Gestational urinary BPA concentrations were lower among women who completed the follow-up assessments, compared with those who did not (geometric mean: 2.0 vs 2.5 $\mu\text{g/L}$). However, creatinine-standardized concentrations were similar for women with complete (geometric mean: 2.4 $\mu\text{g/g}$) and incomplete (geometric mean: 2.5 $\mu\text{g/g}$) follow-up data. Children from families with lower maternal education or household income had higher BASC-2 and BRIEF-P scores at 3 years of age (Table 1).

Maternal BPA concentrations were relatively stable between the first sample and birth (Fig 1 and Table 2). Children's urinary BPA concentrations decreased from 1 to 3 years of age, and this decrease became more apparent after creatinine standardization. Children's urinary BPA concentrations were higher and more variable than maternal concentrations. We observed weak correlations between pairs of time-specific maternal-maternal, child-child, and maternal-

child urinary BPA concentrations (Pearson $R < 0.25$), which became weaker after creatinine standardization (Pearson $R < 0.18$).

The mean creatinine-standardized gestational and childhood BPA concentrations exhibited a weak correlation (Pearson $R = 0.11$). Mean BPA concentrations from gestation or childhood were similar in magnitude to individual measurements but were less variable.

Urinary BPA Concentrations and Behavior/Executive Function

The 3-knot, restricted, cubic, polynomial splines revealed approximately linear relationships between \log_{10} -transformed urinary BPA concentrations and BASC-2/BRIEF-P scores (Fig 2; childhood data not shown). Therefore, we chose to characterize BPA concentrations as continuous \log_{10} -transformed variables.

FIGURE 1

Box plots of nonstandardized and creatinine-standardized urinary BPA concentrations. Creatinine-standardized urinary BPA concentrations were calculated by dividing urinary BPA concentrations by urinary creatinine concentrations, to control for urine dilution, whereas nonstandardized concentrations were not. Whiskers represent the minimum and 1.5 times the interquartile range. The tops and bottoms of the boxes represent the 75th and 25th percentiles, respectively. The lines in the boxes represent the medians, and the diamonds represent the means. Circles represent extreme observations (>1.5 times the interquartile range).

With adjustment for confounders, gestational BPA concentrations were positively associated with BASC-2 anxiety, hyperactivity, and depression scale scores (Table 3). The magnitude of these associations was greater among

girls, compared with boys ($P < .10$). Anxiety and depression associations for girls were almost twice as large as associations for the whole sample, whereas associations for boys were close to the null. Notably, gestational

BPA concentrations were associated with increases in BASC-2 hyperactivity scores among girls ($\beta = 9.1$ [95% confidence interval [CI]: 3.1–15]) but decreases among boys ($\beta = -6.3$ [95% CI: -12 to -0.6]). In general, associations between childhood urinary BPA concentrations and BASC-2 scores were positive in direction, and 95% CIs straddled the null value. We did not observe evidence that childhood BPA concentrations were modified by child gender.

Gestational BPA concentrations were positively associated with emotional control and inhibition scores on the BRIEF-P with adjustment for confounders (Table 4). The magnitudes of associations were similar to those observed for the BASC-2. Associations between gestational BPA concentrations and emotional control and inhibition scale scores were larger among girls, compared with boys (interaction $P \leq .10$). Associations between childhood urinary BPA concentrations and BRIEF-P scores were null, and child gender did not modify these associations.

Adjustment for confounders shifted most point estimates for associations between gestational BPA exposure and BASC-2/BRIEF-P scores up, and in some cases through the null. Conversely, adjustment for confounders shifted most estimated associations between childhood BPA exposure and neurobehavioral scores down, and sometimes through the null. BPA estimates from unadjusted and adjusted models had similar precision, as evidenced by the 95% CI width.

Secondary Analyses

The inclusion of both gestational and childhood urinary BPA concentrations in the same model did not alter the pattern of observed results, and neither did adjustment for maternal IQ, parity, or duration of breastfeeding (results

not shown). We observed a similar pattern of results when we limited our analyses to women ($n = 215$) and children ($n = 154$) with all 3 urine samples during gestation and childhood, respectively. The exclusion of women ($n = 32$) or children ($n = 13$) with dilute or concentrated urine did not change the pattern of results.

DISCUSSION

Gestational urinary BPA concentrations were associated with some neurobehavioral measures at 3 years of age in this cohort. In particular, gestational BPA exposure was associated with higher scores for measures of anxiety, hyperactivity, emotional control, and behavioral inhibition. Similar to our previous findings, the effects of gestational BPA exposure on these behavioral domains were larger among girls than boys.² The different responses to gestational BPA exposure were especially pronounced for hyper-

activity; girls exhibited increases in hyperactivity, and boys exhibited decreases in hyperactivity. In contrast, childhood urinary BPA concentrations were less important predictors of behavior or executive functions in this study.

The findings presented are consistent with numerous studies demonstrating altered neurobehavior among BPA-exposed animals.^{14,38} Gestational BPA exposures might affect endocrine or other neurotransmitter pathways and disrupt sexual differentiation of the brain, to alter behavior in a gender-dependent manner.^{39,40} However, the exposures and behavioral end points used in some animal studies might not be relevant or comparable to human cases.⁴¹ A recent epidemiological study suggests that gestational BPA exposure may be associated with impaired social behaviors in children.⁴² However, the authors did not find that

their associations were modified by child gender.

The association of anxious, hyperactive, and depressive behaviors with gestational BPA exposure seems paradoxical at first; however, there is substantial comorbidity between attention-deficit/hyperactivity disorder, depression, and anxiety disorders.⁴³ The pattern of observed associations suggests that gestational BPA exposure may affect neurobehavioral domains associated with behavioral regulation. Additional research using neuropsychologically based measures of these domains would enhance our understanding of BPA-neurobehavior relationships.

Our results suggested that girls in this cohort were more sensitive to gestational BPA exposures than were boys. This pattern should be interpreted cautiously, given the imprecision of the observed associations among girls

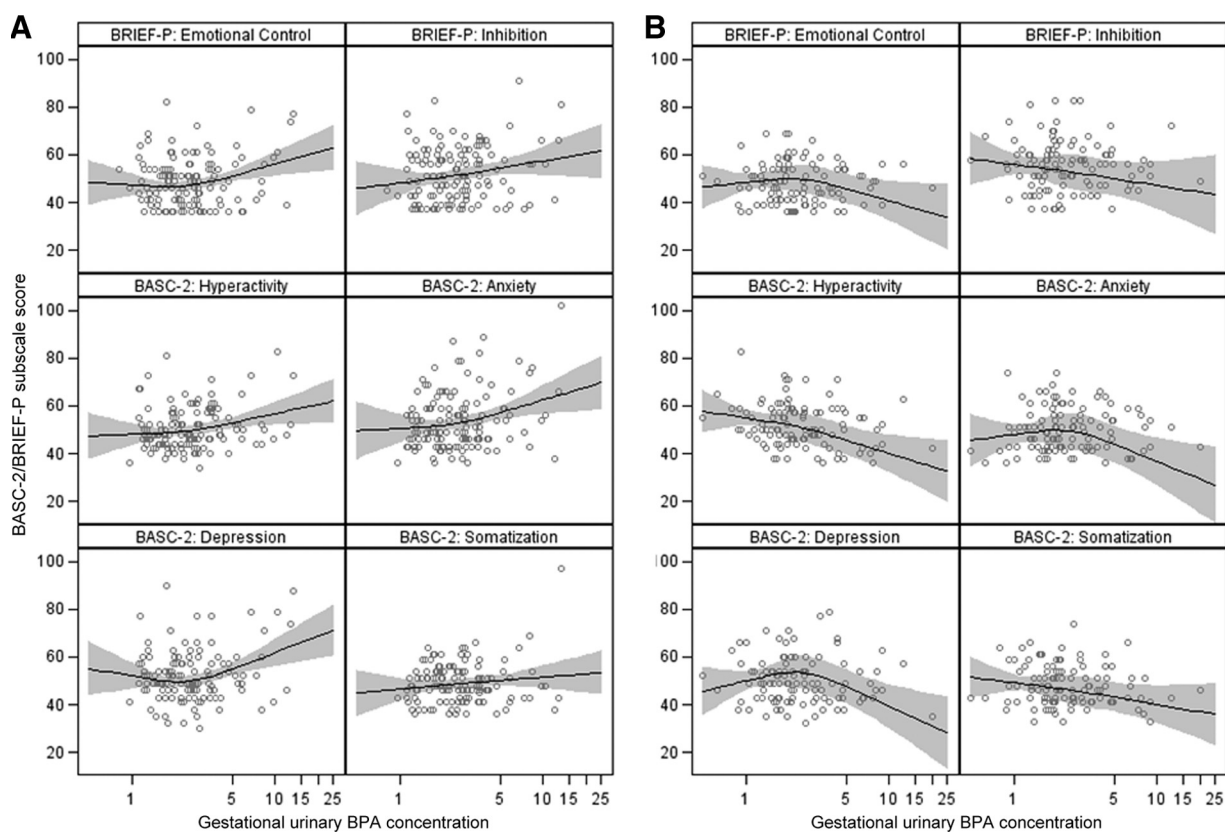

FIGURE 2

Scatterplot and adjusted smoothed regression of gestational urinary BPA concentrations and BASC-2/BRIEF-P subscale scores at 3 years of age: A, girls; B, boys. Models were adjusted for race (white, black, or other), household income (continuous, in thousands of dollars), education (graduate/professional school, bachelor's degree, some college, high school, or less than high school), marital status (married or unmarried), depressive symptoms during pregnancy (continuous), Home Observation for Measurement of the Environment scores (continuous), \log_{10} -transformed mean gestational serum cotinine concentrations, and \log_{10} -transformed mean gestational low molecular weight urinary phthalate concentrations. The relationship was smoothed by using a restricted, cubic, polynomial spline with knots at the 10th, 50th, and 90th percentiles of the gestational urinary BPA concentrations. Black lines represent mean regression lines, gray bands are 95% CIs, and dots are raw data.

and the low statistical power for interactions between gender and BPA exposures. This finding is intriguing, however, given the endocrine-disrupting nature of BPA. Future studies should examine other sexually dimorphic behaviors and should address whether boys and girls have different levels of susceptibility to BPA at different periods of development.

The results from analyses using the BRIEF-P corroborated our findings with the BASC-2 and suggest that associations between gestational BPA exposure and behavior might be related to poor behavioral regulation. Alternatively, this result might reflect the shared correlation between these 2 measures, rather than deficits in

performance-based measures of executive function.^{25,44} The BRIEF-P may merely serve as an additional measure of problem behaviors.

The generalizability of our findings might vary according to predictors of neurobehavior and levels of BPA exposure in selected target populations. Consistent with findings in the United States, children from lower socioeconomic backgrounds had scores indicative of more behavioral and executive function impairment. Our observed urinary BPA concentrations were similar to those measured in other studies with pregnant women.^{3,45,46} Children's urinary BPA concentrations at 1, 2, and 3 years of age were higher than concentrations reported

for adults but were slightly lower than concentrations observed among 6- to 11-year-old children in previous studies.^{47,48} Higher BPA concentrations in children could be attributable to pharmacokinetic factors or increased food consumption per unit of body mass.²⁴

Accurate assessment of BPA exposure during the correct period of susceptibility is difficult. One of the primary strengths of this study is that we collected 6 spot urine samples from mothers and their children and averaged ≥ 2 urinary BPA concentrations during gestation or childhood, to reduce exposure variability. BPA concentrations in multiple spot urine samples still may ex-

Mean childhood BPA level (<i>n</i> = 225)				
Aggression scale	2.7 (−1.3 to 6.6)	1.6 (−2.4 to 5.7)	0.7 (−4.8 to 6.2)	3.1 (−2.8 to 9.1)
Hyperactivity scale	0.3 (−3.0 to 3.7)	−1.0 (−4.4 to 2.4)	−1.2 (−5.8 to 3.3)	0.5 (−4.4 to 5.4)
Anxiety scale	2.7 (−1.6 to 6.9)	2.9 (−1.5 to 7.4)	1.3 (−4.7 to 7.4)	3.3 (−3.1 to 9.8)
Depression scale	4.3 (0.4 to 8.2)	3.0 (−1.1 to 7.1)	2.8 (−2.8 to 8.4)	2.9 (−3.1 to 8.9)
Somatization scale	3.3 (0.0 to 6.6)	1.6 (−1.8 to 5.1)	2.0 (−2.7 to 6.8)	1.1 (−4.0 to 6.2)
Attention scale	1.5 (−1.5 to 4.4)	1.1 (−2.0 to 4.3)	1.1 (−3.2 to 5.4)	2.3 (−2.3 to 6.9)

Models were adjusted for race (white, black, or other), household income (continuous, in thousands of dollars), education (graduate/professional school, bachelor's degree, some college, high school, or less than high school), marital status (married or unmarried), depressive symptoms during pregnancy (continuous), Home Observation for Measurement of the Environment scores (continuous), log₁₀-transformed mean gestational serum cotinine concentrations, and log₁₀-transformed mean gestational low-molecular weight urinary phthalate concentrations.

^a Model includes child gender and a BPA level–child gender interaction term.

^b For gender–BPA level interaction, *P* < .10.

TABLE 4 Unadjusted and Adjusted Changes in BRIEF-P Scores at 3 Years of Age With 10-Fold Increases in Creatinine-Standardized Gestational and Childhood Urinary BPA Concentrations

Emotional Control Scale	Change in BRIEF-P Score, Estimate (95% CI)			
	All, Unadjusted	All, Adjusted	Girls, Adjusted ^a	Boys, Adjusted ^a
Mean gestational BPA level (<i>n</i> = 237)				
Emotional control scale	2.9 (−1.7 to 7.4)	4.9 (0.5 to 9.3)	9.1 (2.8 to 15)	1.1 (−5.1 to 7.2) ^b
Inhibit scale	2.3 (−3.2 to 7.8)	4.1 (−1.3 to 9.5)	9.3 (1.8 to 17)	0.4 (−7.0 to 7.8) ^b
Plan/organize scale	0.2 (−5.4 to 5.8)	1.1 (−4.4 to 6.7)	5.4 (−2.5 to 13)	−2.2 (−10 to 5.5)
Shift scale	1.4 (−3.6 to 6.4)	3.1 (−2.0 to 8.2)	5.5 (−1.7 to 13)	1.4 (−5.7 to 8.5)
Working memory scale	−0.6 (−6.6 to 5.5)	0.6 (−5.4 to 6.5)	4.2 (−4.3 to 12)	−2.4 (−11 to 5.9)
Mean childhood BPA level (<i>n</i> = 223)				
Emotional control scale	3.9 (0.3 to 7.5)	2.5 (−1.2 to 6.2)	1.6 (−3.4 to 6.7)	4.1 (−1.3 to 9.5)
Inhibit scale	1.8 (−2.5 to 6.0)	−0.7 (−5.1 to 3.8)	−1.2 (−7.1 to 4.7)	2.2 (−4.2 to 8.5)
Plan/organize scale	3.7 (−0.7 to 8.0)	1.7 (−2.9 to 6.3)	1.4 (−4.8 to 7.7)	3.3 (−3.3 to 10)
Shift scale	1.7 (−2.2 to 5.6)	0.0 (−4.2 to 4.2)	0.2 (−5.5 to 5.9)	1.0 (−5.1 to 7.1)
Working memory scale	3.3 (−1.4 to 8.0)	1.7 (−3.3 to 6.6)	1.2 (−5.4 to 7.9)	3.5 (−3.7 to 11)

Models were adjusted for race (white, black, or other), household income (continuous, in thousands of dollars), education (graduate/professional school, bachelor's degree, some college, high school, or less than high school), marital status (married or unmarried), depressive symptoms during pregnancy (continuous), Home Observation for Measurement of the Environment scores (continuous), log₁₀-transformed mean gestational serum cotinine concentrations, and log₁₀-transformed mean gestational low-molecular weight urinary phthalate concentrations.

^a Model includes child gender and a BPA–child gender interaction term.

^b For gender–BPA level interaction, *P* < .10.

hibit substantial within-person variability but may classify BPA exposure accurately over time scales of days to weeks.^{22,47,49,50} With the assumption of nondifferential exposure misclassification, this error would result in null-biased estimates.⁵¹ Integrated exposure measures such as mean BPA concentrations might reduce misclassification rates, but they would decrease the ability to identify short time-

sensitive windows of development. Future studies should consider the importance of collecting multiple or integrated urinary concentration measurements, to improve exposure classification during critical windows of neurodevelopment.

We adjusted for a variety of confounders, including factors that are difficult to measure, such as the caregiving environment and biomarkers of other en-

vironmental toxicants. Adjustment did not greatly affect the magnitude of most estimates, which suggests that confounding by these factors was not an important source of bias. However, additional, unidentified, confounding factors, including other hormonally active chemicals that vary with BPA or heritable personality traits that influence BPA exposure and childhood behavior, might explain some of the observed associations.

Our sample size was modest, which reduced our statistical power to test for gender modification and led to wide CIs. In addition, we examined many exposure-outcome associations, which increased the likelihood that our results might include the null value through chance alone. Instead of applying mathematical corrections for multiple comparisons, such as the Dunn-Bonferroni correction, we avoided strict application and interpretation of statistical significance thresholds (such as the 95% CI excluding the null value).⁵² Instead, we focused on the patterns, magnitudes, and consistency of our results and compared those factors with findings from our previous studies and experimental studies with animals.^{38,42}

The clinical relevance of these findings is unclear at this point. Despite this uncertainty, clinicians can advise con-

cerned patients to reduce their exposure, as well as cautioning that it is difficult to avoid all sources of exposure and the health consequences of BPA exposure are not fully understood. BPA exposure can be reduced by avoiding canned and packaged foods, receipts, and polycarbonate bottles with the recycling symbol 7.^{22,38,53,54}

CONCLUSIONS

The results of this study suggest that gestational BPA exposure might be associated with anxious, depressive, and hyperactive behaviors related to impaired behavioral regulation at 3 years of age. This pattern was more pronounced for girls, which suggests that they might be more vulnerable to gestational BPA exposure than boys. In contrast, childhood BPA exposure did not exhibit associations with behavior and executive function at 3 years of age. There is considerable debate re-

garding the toxicity of low-level BPA exposure, and the findings presented here warrant additional research.

ACKNOWLEDGMENTS

This study was funded in part by a Children's Environmental Health Center Grant from the National Institute of Environmental Health Sciences and the US Environmental Protection Agency (grant P01 ES11261). Additional funding came from National Institute of Environmental Health Sciences training grants T32 ES007018 and T32ES007069. The funders had no role in the study design, data collection or analysis, decision to publish, or preparation of the manuscript.

We acknowledge the technical assistance of A. Bishop, X. Zhou, R. Hennings, and T. Jia (CDC, Atlanta, GA) in measuring the urinary concentrations of BPA.
